#### ABSTRACT

#### OPTIMIZATION OF DERIVATION JOBS AND MODERNIZATION OF NIGHTLY CI BUILD I/O TESTS FOR THE ATLAS EXPERIMENT

Arthur C. Kraus, M.S.

Dr. Jahred Adelman, Director

The High-Luminosity LHC (HL-LHC) is a phase of the LHC that is expected to start toward the end of the decade. With this comes an increase in data taken per year that current software and computing infrastructure, including I/O, is being prepared to handle. The ATLAS experiment's Software Performance Optimization Team has areas in development to improve the Athena software framework that is scalable in performance and ready for wide-11 spread HL-LHC era data taking. One area of interest is optimization of derivation production 12 jobs by improving derived object data stored to disk by about 4-5% by eliminating the upper-13 limit on TTree basket buffers, at the expense of an increase in memory usage by about 11%. 14 Athena and the software it depends on are updated frequently, and to synthesize changes 15 cohesively there are scripts, unit tests, that run which test core I/O functionality. This thesis also addresses a project to add a handful of I/O unit tests that exercise features exclusive 17 to the xAOD Event Data Model (EDM) such as writing and reading object data from the previous EDM using transient and persistent data. These new unit tests also include and 19 omit select dynamic attributes to object data during the component accumulator step.

#### CHAPTER 1

28

29

41

#### INTRODUCTION

Particle physics is the branch of physics that studies the fundamental constituents of matter and the forces governing their interactions. The field started as studies in electromagnetism, radiation, and further developed with the discovery of the electron. What followed was more experiments to search for new particles, new models to describe the results, and new search techniques which demanded more data. The balance in resources for an experiment bottlenecks how much data can be taken, so steps need to be taken to identify interesting interactions and optimize the storage and processing of this data. This thesis investigates software performance optimization of the ATLAS experiment at CERN. Specifically, ways to modernize and optimize areas of the software framework, Athena, to improve input/output (I/O) performance during derivation production and create new tests that catch when specific core I/O functionality is broken.

#### 1.1 LHC and The ATLAS Detector

The Large Hadron Collider (LHC), shown in Figure ??, is a particle accelerator spanning a 26.7-kilometer ring that crosses between the France-Switzerland border at a depth between 50 and 175 meters underground. [LHC'faq'guide] The ATLAS experiment, shown in Figure ??, is the largest LHC general purpose detector, and the largest detector ever made for particle collision experiments. It's 46 meters long, 25 meters high and 25 meters wide. [ATLAS'Fact'Sheet] The ATLAS detector is comprised of three main sections, the inner detector, calorimeters and the muon detector system.

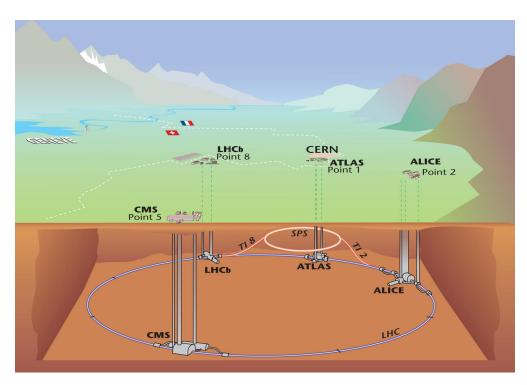

Figure 1.1: Illustration of the LHC experiment sites on the France-Switzerland border.[LHC'Illustration]

The inner detector measures the direction, momentum and charge of electrically charged 49 particles. Its main function is to measure the track of the charged particles without destroy-50 ing the particle itself. The first point of contact for particles emerging from pp-collisions from 51 the center of the ATLAS detector is the pixel detector. [PixelDetector'2008] It has over 92 52 million pixels and is radiation hard to aid in particle track and vertex reconstruction. When 53 charged particles pass through a pixel sensor, it ionizes the one-sided doped-silicon wafer to 54 produce an excited electron will then occupy the conduction band of the semiconductor pro-55 ducing an electron-hole pair, leaving the valence band empty. [KnollRadDetection] This hole in the valence band together with the excited electron in the conduction band is called an electron-hole pair. The electron-hole pair is in the presence of an electric field, which will induce drifting of the electron-hole pair, drifting that will generate the electric current to be measured.

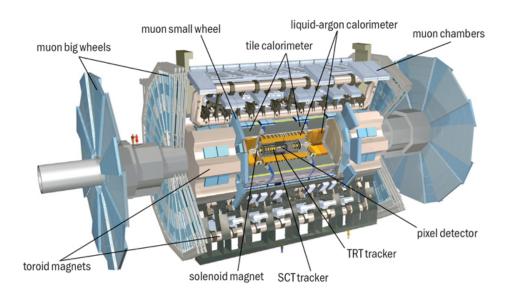

Figure 1.2: Overview of the ATLAS detectors main components.[ATLAS'Illustration]

Surrounding the pixel detector is the SemiConductor Tracker (SCT), which uses 4,088 modules of 6 million implanted silicon readout strips.[ABDESSELAM2006642] Both the pixel detector and SCT measure the path particles take, called tracks. While the pixel detector has measurement precision up to  $10\mu m$ , the SCT has precision up to  $25\mu m$ .

The final layer of the inner detector is the transition radiation tracker (TRT). The TRT is made of a collection of tubes made with many layers of different materials with varying indices of refraction. The TRT's straw walls are made of two  $35\mu m$  layers comprised of  $6\mu m$  carbon-polymide,  $0.20\mu m$  aluminum, and a  $25\mu m$  Kapton film reflected back.[TRT'2008] The straws are filled with a gas mixture of  $70\%\text{Xe} + 27\%\text{CO}_2 + 3\%\text{O}_2$ . Its measurement precision is around  $170\mu m$ . Particles with relativistic velocities have higher Lorentz  $\gamma$ -factors (see Equation (??)). The TRT uses varying materials to discriminate between heavier particles, which have low  $\gamma$  and radiate less, and lighter particles, which have higher  $\gamma$  and radiate more.[Mindur:2139567]

$$\gamma = \frac{1}{\sqrt{1 - \frac{v^2}{c^2}}}\tag{1.1}$$

There are two main calorimeters for ATLAS, the Liquid Argon (LAr) calorimeter and the 74 Tile Hadronic calorimeter. The LAr calorimeter surrounds the inner detector and measures 75 the energy deposits of electrons, photons and hadrons (quark bound states, such as baryons 76 qqq and mesons  $q\bar{q}$ ). It layers various metals to intercept the incoming particles to produce 77 a shower of lower energy particles. The lower energy particles then ionize the liquid argon 78 that fill the barrier in between the metal layers to produce a current that can be read out. 79 The Tile calorimeter surrounds the LAr calorimeter and is the largest part of the ATLAS 80 detector weighing in around 2900 tons. Particles then traverse through the layers of steel and 81 plastic scintillating tiles. When a particle hits the steel, a cascade of secondary particles is 82 generated, and the plastic scintillators will produce photons whose current can be measured.

#### 1.2 ATLAS Trigger and Data Acquisition (DAQ)

84

The LHC produces pp-collisions at a rate of 40 MHz, each collision is an "event". The 85 ATLAS Trigger system is responsible for quickly deciding what events are interesting for physics analysis. The Trigger system is divided into the first- and second-level triggers and 87 when a particle activates a trigger, the trigger makes a decision to tell the Data Acquistion 88 System (DAQ) to save the data produced by the detector. The first-level trigger is a hardware trigger that decides, within  $2.5\mu s$  after the event, if it's a good event to put into a storage 90 buffer for the second-level trigger. The second-level trigger is a software trigger that decides 91 within  $200\mu s$  and uses around 40,000 CPU-cores and analyses the event to decide if it is 92 worth keeping. The second-level trigger selects about 1000 events per second to keep and 93 store long-term. [Trigger-DAQ] The data taken by this Trigger/DAQ system is raw and not yet in a state that is ready for analysis, but it is ready for the reconstruction stage.

The amount of data taken at ATLAS is substantial. ATLAS sees more than 3.2 PB of raw data each year, each individual event being around 1.6 MB.[ATLAS'Fact'Sheet] All of the data produced by LHC experiments, especially ATLAS, has to be sent to the LHC Computing Grid (LCG). The increase in data means more resources from the Grid will be needed, so optimization is an essential part of ensuring scalability of the data able to be taken in by the experiment. Reconstructed AOD are then processed through derivation jobs that reduced AODs from  $\mathcal{O}(1)$  MB per event to  $\mathcal{O}(10)$  kB per event, creating Derived AOD (DAOD).

#### 1.3 HL-LHC and Future Needs in Computation

104

105

106

107

108

109

The High-Luminosity LHC (HL-LHC) is the upgrade to LHC that anticipates more events and more data taken than ever before. The goal is to reach a luminosity of  $350fb^{-1}$ , which is forecasted to be reached gradually by around 2040.[HL-LHC'Tech'design] The HL-LHC era is projected to demand anywhere from 6-10 times data stored per year, so any attempt to save on disk storage will help.[ATLAS'HL-LHC'projections]

One area of research to account for this flood of new data is in the development of 110 the ROOT N-Tuple (RNTuple) I/O subsystem, which is a new storage format for high-111 energy physics data seeking to replace ROOT TTree. The RNTuple is a columnar-based 112 storage format that is optimized for data storage and processing. It's been shown to 113 outperform TTree I/O subsystem and other storage formats in file size (by about 15%), 114 throughput, and compression, but still has more development before full implementation 115 into the analysis pipeline. [RNTuple'Lopez-Gomez'2023] [RNTuple'Blomer] Addition-116 ally, there's a push to utilize GPUs and other accelerators in conjunction with CPUs to 117 process track reconstruction and AOD derivation. Also being developed are software frame-118

work updates, such as AthenaMT, to make the single-threaded CPU programs multi-thread ready.[AthenaMT'Leggett'2017]

#### CHAPTER 2

#### I/O TOOLS

121

122

130

The Trigger/DAQ system sends and saves data from the detector to a persistent data storage solution. It's at this stage where the data isn't yet ready for an effective analysis, so what needs to happen is the data needs to be reconstructed and consolidated into physics objects, or Analysis Object Data (AOD) files. Creating AODs from data requires significant computation power and Athena is the software framework that plays a significant role in this process. This chapter will cover some of the important software tools used by ATLAS to run derivation jobs, as well as introduce data structures that represent event information.

#### 2.1 Athena and ROOT

Athena is the open-source software framework for the ATLAS experiment.[athena] It uses on other software such as ROOT, Geant4 and other software as part of the LCG software stack. Athena manages ATLAS production workflows which include event generation, simulation of data, reconstruction from hits, and derivation of reconstructed hits.[athenadocs]

It also provides some in-house based analysis tools as well as tools for specifically ROOT based analysis.

137 CMake and Make are open-source software that is used to build Athena, ROOT, and
138 other software. A sparse build is a way to make changes to an individual package of code
139 without having to recompile the entire framework at once, which saves time and resources.
140 A user can create a text file identifying the path to the package modified, and the sparse
141 build for Athena will proceed upon issuing the following commands:

```
cmake -DATLAS_PACKAGE_FILTER_FILE=../package_filters.txt ../athena/
Projects/WorkDir/
make -j
```

Where ../package\_filters.txt is the text file containing the path to the package modified, and ../athena/Projects/WorkDir/ is the path to the Athena source.

AthenaPOOL is data storage architecture suite of packages within Athena that provide conversion services. It originated as a separate project to serve as a layer between the transient data, stored in memory, used by the software framework and the data stored permanently, or persistently. The transient/persistent style of representing event data will be further explained in § ??.

An important step throughout the development of Athena is to ensure any new changes 154 to the codebase won't overrule the functionality of core features to the present workflows. 155 One of the ares needed to be tested before and upon merging of any new changes to Athena 156 is the I/O functionality, or the performance of reading and writing of stored objects within a 157 broader context of various jobs, i.e. reconstruction or derivation. These are unit tests which 158 are scripts written in Python and call upon algorithms written in C++. The python scripts 159 are used to set the job options for the algorithms added to the component accumulator (CA), 160 job options like flag definitions, input and output file names, and other algorithm specific 161 options. While CA is a more general mechanism to run any kind of job with Athena, it's 162 within the scope of this thesis where the focus is on testing core I/O functionality of the new 163 event data model. A general CA script written in pseudocode would take the form: 164

```
# Import Packages

from AthenaConfiguration.AllConfigFlags import initConfigFlags

from AthenaConfiguration.ComponentFactory import CompFactory

from OutputStreamAthenaPool.OutputStreamConfig import OutputStreamCfg,

outputStreamName
```

```
171
        # Set Job Options
172
        outputStreamName = "StreamA"
173
        outputFileName = "output.root"
174
175
        # Setup flags
176.0
        flags = initConfigFlags()
177
        flags.Input.Files = ["input.root"]
178
        flags.addFlag(f"Output.{streamName}FileName", outputFileName)
179
        # Other flags
180
        flags.lock()
181
182
        # Main services
183
        from AthenaConfiguration.MainServicesConfig import MainServicesCfg
184
        acc = MainServicesCfg( flags )
185
1862
        # Add algorithms
1872
        acc.addEventAlgo( CompFactory.MyAlgorithm(MyParameters) )
1882
189
        # Run
1902
        import sys
1912
        sc = acc.run(flags.Exec.MaxEvents)
192
        sys.exit(sc.isFailure())
193
194
```

ROOT is an open-source software framework used for high-energy physics analysis at CERN.[ROOT'about] It uses C++ objects to save, access, and process data brought in by the various experiments based at the LHC, the ATLAS experiment uses it in conjunction with Athena. ROOT largely revolves around organization and manipulation of TFiles and TTrees into ROOT files. A TTree represents a columnar dataset, and the list of columns are called branches. The branches have memory buffers that are automatically allocated by ROOT.

These memory buffers are divided into corresponding baskets, whose size is designated during memory allocation. More detail on branch baskets are explored in Chapter ?? and ??.

#### 2.1.1 Continuous Integration (CI) and Development

CI is a software development practice where new code is tested and validated upon each

203

204

214

merge to the main branch of a repository. Every commit to the main branch is automatically
built and tested for specific core features that are required to work with the codebase. This
helps to ensure that the codebase is working as intended and that the new code is compatible
with the existing codebase.

Athena is hosted on GitLab and developed using CI with an instance of Jenkins, called
ATLAS Robot, which builds and tests the new changes within a merge request interface.
ATLAS Robot will then provide a report of the build and test results. If the build or test
fail, ATLAS Robot will provide a report of which steps failed and why. This allows for early

#### 2.2 TTree Object

detection of issues before the nightly build is compiled and tested.

A TTree is a ROOT object that organizes physically distinct types of event data into branches. Branches hold data into dedicated contiguous memory buffers, and those memory buffers, upon compression, become baskets. These baskets can have a limited size and a set minimum number of entries. The Athena default basket size at present is 128 kB, and the default minimum number of entries is 10.

One function relevant to TTree is Fill(). Fill() will loop over all of the branches in the
TTree and compresses the baskets that make up the branch. This removes the basket from

memory as it is then compressed and written to disk. It makes reading back branches faster
as all of the baskets are stored near each other on the same disk region. [ROOT'TTree]

AutoFlush is a function that tells the Fill() function after a designated number of
entries of the branch, in this case vectors, to flush all branch buffers from memory and save
them to disk.

#### 2.3 Derivation Production Jobs

A derivation production job takes AODs, which comes from the reconstruction step at  $\mathcal{O}(1 \text{ MB})$  per event, and creates a derived AOD (DAOD) which sits at  $\mathcal{O}(10 \text{ kB})$  per event. Derivation production is a necessary step to make all data accessible for physicists doing analysis as well as reducing the amount of data that needs to be processed. While derivations are reduced AODs, they often contain additional information useful for analysis, such as jet collections and high-level discriminants.[PHYSLITE'A'new'2024] Athena provides two types of output files from a derivation job, PHYS and PHYSLITE. Figure ?? shows the object composition of a PHYS and PHYSLITE  $t\bar{t}$  sample. PHYS output files, at 40.0 kB

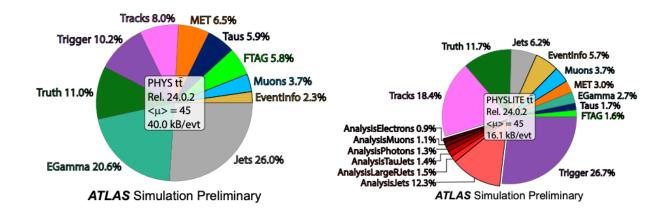

Figure 2.1: Object composition of a PHYS and PHYSLITE  $t\bar{t}$  sample from Run 3.

per event, is predominantly made of jet collections, while PHYSLITE, at 16.1 kB per event,
has more trigger and track information. There is ongoing work to reduce the amount of
Trigger information in PHYSLITE which would help further reduce the file size saved to
disk. PHYSLITE, being the smallest file of the two, sees the largest effect upon attempts of
optimization. These jobs can demand heavy resource usage on the GRID, so optimization
of the AOD/DAODs for derivation jobs can be vital.

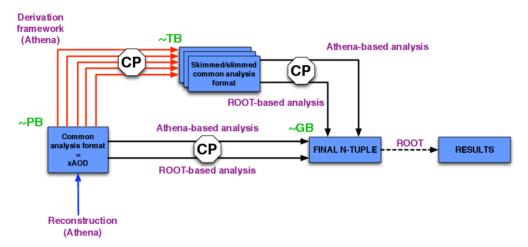

Figure 2.2: Derivation production from Reconstruction to Final N-Tuple[DAOD'Laycock'2014]

The derivation framework is sequence of steps that are performed on the AODs to create the DAODs. Skimming is the first step in the derivation framework, and it's responsible for removing whole events based on pre-defined criteria. Thinning is the second step, and it removes whole objects based on pre-defined criteria. Lastly slimming removes variables from objects uniformly across events.

#### 2.4 Event Data Models

247

An Event Data Model (EDM) is a collection of classes and their relationships to each other that provide a representation of an event detected with the goal of making it easier

to use and manipulate by developers. An EDM is how particles and jets are represented in memory, stored to disk, and manipulated in analysis. It's useful to have an EDM because it brings a commonality to the code, which is useful when developers reside in different groups with various backgrounds. An EDM allows those developers to more easily debug and communicate issues when they arise.

#### 2.4.1 Transient/Persistent (T/P) EDM

255

One of the previous EDM schemas used by ATLAS concerned a dual transient/persis-256 tent status of AOD. With this EDM, the AOD was converted into an ntuple based format called D3PDs. While this conversion allowed for fast readability and partial read for 258 efficient analysis in ROOT, it left the files disconnected from the reconstruction tools found in Athena. [Athena'x AOD'design] When transient data was present in memory, it could have 260 information attatched to the object and gain in complexity the more it was used. Transient 261 data needed to be simplified before it could become persistent into long-term storage (sent to 262 disk). ROOT had trouble handling the complex inheritance models that would come up the 263 more developers used this EDM. Before the successor to the T/P EDM was created, ATLAS 264 physicists would convert data samples using the full EDM to a simpler one that would be 265 directly readable by ROOT. This would lead to duplication of data and made it challenging 266 to develop and maintain the analysis tools to be used on both the full EDM and the reduced 267 ones. Additionally, converting from transient to persistent data was an excessive step which 268 was eventually removed by the adoption of using an EDM that blends the two stages of data 269 together, this was dubbed the xAOD EDM. 270

#### 2.4.2 xAOD EDM

271

The xAOD EDM is the successor to the T/P EDM and brings a number of improvements. 272 This EDM, unlike T/P, is usuable both on Athena and ROOT. It's easier to pick up for 273 analysis and reconstruction. The xAOD EDM has the ability to add and remove variables 274 within an ItemList at runtime, specified in the CA script, these variables are "decorations." 275 The xAOD EDM use two types of objects handle data, interface objects and payload 276 objects. Interfaces act as an interface for the user to access the object but without its stored 277 data. This differs from T/P where the user would have to load an object into memory to access the object. If the user wanted to delay the loading of data into memory, they could 279 use the interface object to do so. The payload object contains the data for the interface 280 object and is allocating contiguous blocks of memory. Payload classes are often referred to 281 as auxiliary storage. 282

The specific data structure used by ATLAS is the ROOT TTree, but the EDM is agnostic to the type of data structure used. ATLAS specific libraries are not required to handle files written in the xAOD format since the payload can be read directly from the contiguous allocation of memory, a central tenent of the xAOD EDM. This allows for the separation of ATLAS specific analysis frameworks and the preferred analysis tool of the user. More information on how the xAOD EDM is deployed into unit tests in § ??.

#### CHAPTER 3

289

290

303

#### TOY MODEL BRANCH STUDY

Building a toy model for derivation production jobs offers a simplified framework to 291 effectively simulate and analyze the behavior of real and Monte Carlo (MC) data under 292 techniques of optimization aimed to study. One commonality between both data and MC is 293 the data types stored in branches for both is made of a mixture between repeated integer-like data and randomized floating-point data. Intergers are easier to compress than floating-point numbers, so adjusting the mixture of each will yield compression ratios closer to real and MC data. Replicating this mixture in a branch give us an effective model that resemble 297 how current derivation jobs act on real and MC simulated data. These toy model mixtures 298 provide an avenue to test opportunities for optimizing the memory and storage demands 299 of the GRID by first looking at limiting basket sizes and their effects on compression of 300 branches. 301

#### 3.1 Toy Model Compression

#### 3.1.1 Random Float Branches

There were a number of iterations to the toy model, but the first was constructed by filling
a TTree with branches that each have vectors with varying number of random floats to write
and read. Vectors are used in this toy model, as opposed to arrays, because vectors are
dynamically allocated and deallocated, which allows for more flexibility when synthesizing
AOD. This original model had four distinct branches, each with a set number of events

(N=1000), and each event having a number of entries, vectors with 1, 10, 100, and 1000 floats each.

The script can be compiled with gcc or g++ and it requires all of the dependencies that come with ROOT. Alternatively, the script can be run directly within ROOT.

The following function VectorTree() is the main function in this code. What is needed 313 first is an output file, which will be called VectorTreeFile.root, and the name of the tree 314 can simply be myTree. Initializing variables start with the total number of events in the 315 branch, i.e. the number of times a branch is filled with the specified numbers per vectors, 316 N. Additionally the branches have a number of floats per vector, this size will need to be 317 defined as size\_vec\_0, size\_vec\_1, etc. The actual vectors that are being stored into each 318 branch need to be defined as well as the temporary placeholder variable for our randomized 319 floats, vec\_tenX and float\_X respectively. 320

```
321
      void VectorTree() {
322
323
        const int N = 1e4; // N = 10000, number of events
324
        // Set size of vectors with 10<sup>#</sup> of random floats
325
        int size_vec_0 = 1;
326
        int size_vec_1 = 10;
327
        int size_vec_2 = 100;
328
        int size_vec_3 = 1000;
329
330
        // vectors
331
        std::vector<float> vec_ten0; // 10^0 = 1 entry
332
        std::vector<float> vec_ten1; // 10^1 = 10 entries
333
        std::vector<float> vec_ten2; // 10^2 = 100 entries
334
        std::vector<float> vec_ten3; // 10^3 = 1000 entries
335
336
337.
        // variables
```

```
float float_0;
float float_1;
float float_2;
float float_3;
...

float float_3;
}
```

From here, initialize the branches so each one knows where its vector pair resides in memory.

```
347
     void VectorTree() {
348
349
        // Initializing branches
        std::cout << "creating branches" << std::endl;</pre>
351
        tree->Branch("branch_of_vectors_size_one", &vec_ten0);
352
        tree->Branch("branch_of_vectors_size_ten", &vec_ten1);
353
        tree->Branch("branch_of_vectors_size_hundred", &vec_ten2);
        tree->Branch("branch_of_vectors_size_thousand", &vec_ten3);
355
356
     }
357.0
```

One extra step taken during this phase of testing is the disabling of AutoFlush.

359

```
360
3611 void VectorTree() {
3622 ...
3633 tree->SetAutoFlush(0);
3644 ...
```

Disabling AutoFlush allows for more consistent compression across the various sizes of branch baskets. The toy model needed this consistency more than the later tests as these early tests were solely focused on mimicking data procured by the detector and event simulation. The derivation production jobs tested in Chapter ?? were tested with AutoFlush enabled because

- those tests are not as concerned with compression as they are with memory and disk usage.
- Following branch initialization comes the event loop where data is generated and emplaced

into vectors.

372

```
373
      void VectorTree() {
374
375
        // Events Loop
376
        std::cout << "generating events..." << std::endl;</pre>
377
        for (int j = 0; j < N; j++) {</pre>
378
            // Clearing entries from previous iteration
379
            vec_ten0.clear();
380
            vec_ten1.clear();
381
            vec_ten2.clear();
382
            vec_ten3.clear();
383
384
            // Generating vector elements, filling vectors
385
            // Fill vec_ten0
386
            // Contents of the vector:
387
                   {float_0}
            11
388
                   Only one float of random value
389
            float_0 = gRandom->Rndm() * 10; // Create random float value
390
            vec_ten0.emplace_back(float_0); // Emplace float into vector
391
392
            // Fill vec_ten1
39320
            // Contents of the vector:
3942
                   {float_1_0, ..., float_1_10}
            11
395
3963
                   Ten floats, each float is random
            for (int n = 0, n < size_vec_1; n++) {</pre>
3972
                 float_1 = gRandom->Rndm() * 10;
3982
                 vec_ten1.emplace_back(float_1);
39926
            }
40027
```

```
4012
                Do the same with vec_ten2 and vec_ten3, except for
4029
                     vectors with size 100 and 1000 respectively.
403
4043
             // After all branches are filled, fill the TTree with
40532
                     new branches
4063
             tree->Fill();
40734
        }
408
        // Saving tree and file
4098
        tree->Write();
41037
41188
      }
```

Once the branches were filled, ROOT then will loop over each of the branches in the TTree and at regular intervals will remove the baskets from memory, compress, and write the baskets to disk (flushed), as was discussed in Section §??.

As illustrated, the TTree is written to the file which allows for the last steps within this script.

```
void VectorTree() {
420
421
422
         // Look in the tree
423
         tree->Scan();
424
         tree->Print();
425 (
426
        myFile ->Save();
427
        myFile ->Close();
428
      }
429.0
      int main() {
4312
```

Upon reading back the ROOT file, the user can view the original size of the file (Totalfile-size), the compressed file size (File-size), the ratio between Total-file-size and File-size
(Compression Factor), the number of baskets per branch, the basket size, and other information. Filling vectors with entirely random values was believed to yield compression ratios
close to real data, but the results in Figure ?? show changes needed to be made to bring
the branches closer to a compression ratio of  $\mathcal{O}(5)$ . It is evident that branches containing
vectors with purely random floats are more difficult to compress due to the high level of
randomization.

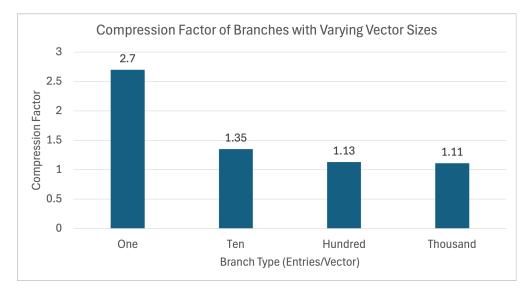

Figure 3.1: Compression factors of N = 1000 entries per branch with random-valued vectors of varying size.

Figure ?? shows compression drop-off as the branches with more randomized floats per vector were present. This is the leading indication that there needs to be more compressible data within the branches.

#### 3.1.2 Mixed-Random Float Branches

447

The branches needed to have some balance between compressible and incompressible data to mimic the compression ratio found in real data. How this was achieved was by filling each vector with different ratios of random floats and repeating integers, which will now be described in detail.

The first change was increasing the total number of events per branch from  $N=10^4$  to  $N=10^5$ , or from 10,000 to 100,000. Mixing of random floats and repeated integer values takes the same script structure as Section § ?? but adjusts the event generation loop.

```
455
      void VectorTree() {
456
457
        // Events Loop
458
        for (int j = 0; j < N; j++) {</pre>
459
            // Clearing entries from previous iteration
460
            vec_ten0.clear();
461
            vec_ten1.clear();
462
            vec_ten2.clear();
463
            vec_ten3.clear();
465
            // Generating vector elements, filling vectors
466
            // Generating vec_ten0
467
               Contents of the vector:
468
            11
                   {float_0}
469
                   Only one float of random value
            // And since there's only one entry, we don't mix the entries.
4716
            float_0 = gRandom->Gaus(0, 1) * gRandom->Rndm();
472
            vec_ten0.emplace_back(float_0);
473
47520
```

```
// Generating vec_ten1
476
                Contents of the vector:
4772
                   {float_1_0, float_1_1, float_1_2, float_1_3, float_1_4, 1,
478
       1, 1, 1, 1}
479
            11
                   5 floats of random values, 5 integers of value 1.
480
            for (int b = 0; b < size_vec_1; b++) {</pre>
4812
                 if (b < size_vec_1 / 2) {</pre>
482
                    float_1 = gRandom->Rndm() * gRandom->Gaus(0, 1);
4832
                    vec_ten1.emplace_back(float_1);
4842
                 } else {
48529
                    float_1 = 1;
486
                    vec_ten1.emplace_back(float_1);
4873
                 }
488
            }
4893
4908
             // Do the same with vec_ten2 and vec_ten3, except for
49B
                     vectors with size 100 and 1000 respectively.
4928
493
4948
             // After all branches are filled, fill the TTree with
495
                    new branches
4960
             tree->Fill();
497
        }
498
        // Saving tree and file
499
        tree->Write();
500
     }
50246
503
```

As shown in the if-statements in lines 14, 25, 36 and 47, if the iterator was less than half of the total number of entries in the vector then that entry had a randomized float put in that spot in the vector, otherwise it would be filled with the integer 1. Having a mixture of

half random floats and half integer 1 led to the larger branches still seeing poor compression, so a new mixture of 1/4 random data was introduced. Even though  $N=10^5$  had the larger branches closer to the desired compression ratio, testing at  $N=10^6$  events improves the accuracy of the overall file size to more closely resemble real data.

Figure ?? shows the difference between compression between the two mixtures at  $N = 10^6$  events. When the number of events is increased from  $N = 10^5$  to  $N = 10^6$ , at the 1/2 random-mixture, the branches with more than one entry per vector see their compression factor worsen. Figure ?? shows a compression ratio hovering around 3 for the larger branches, whereas Figure ?? shows the same branches hovering around 2.

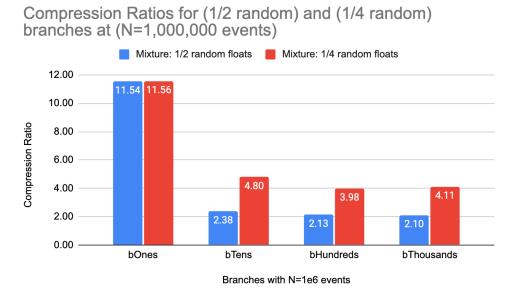

Figure 3.2: Compression Ratios for  $(\frac{1}{2} \text{ random})$  and  $(\frac{1}{4} \text{ random})$  branches at  $(N=10^6 \text{ events})$ 

Unlike the mixture of branches having 1/2 random data, the 1/4 mixture does not see
the same compression effect, but with this mixture we see a compression ratio that is in-line
with real data. This is inline with expectation, more repeated integers within the mixture
makes the branch more compressible, and the more random floats in the mixture will make

### Compression Ratios for (1/2 random) and (1/4 random) branches at (N=100,000 events)

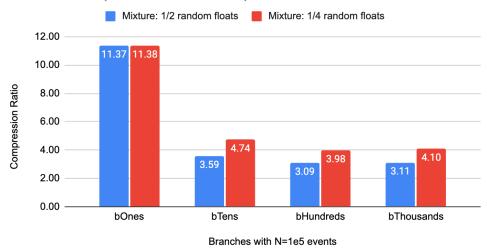

Figure 3.3: Compression Ratios for  $(\frac{1}{2} \text{ random})$  and  $(\frac{1}{4} \text{ random})$  branches at  $(N=10^5 \text{ events})$ 

the branch more difficult to compress. With these mixtures added to the toy model, we can start looking at varying the basket sizes to see how they affect compression.

#### 3.2 Basket-Size Investigation

522

Investigating how compression is affected by the basket size requires us to change the basket size, refill the branch and read it out. Changing the basket sizes was done at the script level with a simple setting after the branch initialization and before the event loop the following code:

```
527
5281
    int basketSize = 8192000;
529 2
    tree->SetBasketSize("*", basketSize);
```

This ROOT-level setting was sufficient for the case of the toy model; testing of the basket size setting both at the ROOT- and Athena-level would be done later using derivation production

jobs in Section §??. The lower bound set for the basket size was 1 kB and the upper bound was 16 MB. The first branch looked at closely was the branch with a thousand vectors with half of them being random floats, see Figure ??.

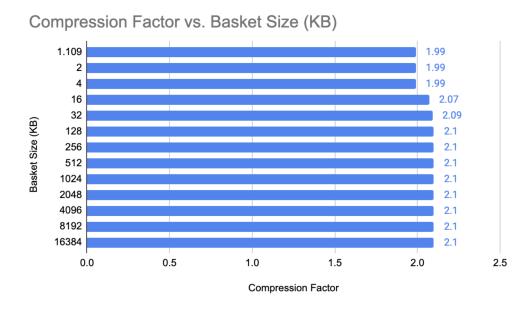

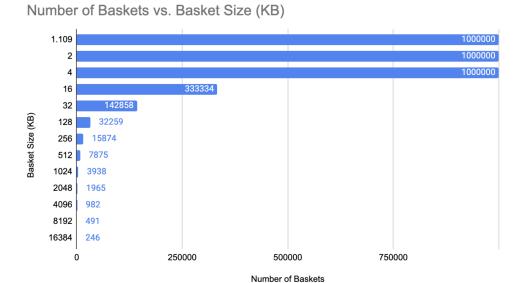

Figure 3.4: Compression Factors vs Branch Size (1000 entries per vector, 1/2 Mixture  $N = 10^6$  events)

Figure ?? and Figure ?? are the first indication that the lower basket sizes are too small 536 to effectively compress the data. For baskets smaller than 16 kB, it is necessary to have as 537 many baskets as events to store all the data effectively. For a mixed-content vector with one 538 thousand entries, containing 500 floats and 500 integers (both are 4 bytes each), its size is 539 approximately 4 kB. ROOT creates baskets of at least the size of the smallest branch entry, 540 in this case the size of a single vector. So even though the basket size was set to 1 or 2 kB, 541 ROOT created baskets of 4 kB. These baskets  $\leq$  4kB have a significantly worse compression 542 than the baskets  $\geq 4$ kB in size, so the focus was shifted toward baskets Once the basket 543 size is larger than the size of a single vector, more than one vector can be stored in a single 544 basket and the total number of baskets is reduced. 545

# Figure 3.5: Number of Baskets vs Branch Size (1000 entries per vector, 1/2 Mixture $N=10^6$ events)

There were different types of configuration to the toy model investigated by this study.

Looking further into the types of mixtures and how they would affect compression are shown
in Figure ?? and ??. Here the same mixtures were used but the precision of the floating point
numbers was decreased from the standard 32 floating-point precision to 16 and 8, making
compression easier.

Each of these sets of tests indicate that after a certain basket size, i.e. 128 kB, there is no significant increase in compression. Having an effective compression at 128 kB, it's useful to stick to that basket size to keep memory usage down. Knowing that increasing the basket size beyond 128 kB yields diminishing returns, it's worth moving onto the next phase of testing with actual derivation production jobs.

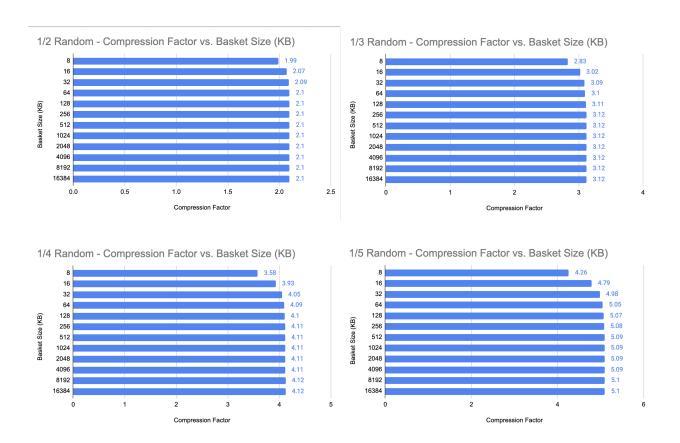

Figure 3.6: Varying Mixtures in 8 point precision - Number of Baskets vs Branch Size  $(N=10^6~{\rm events})$ 

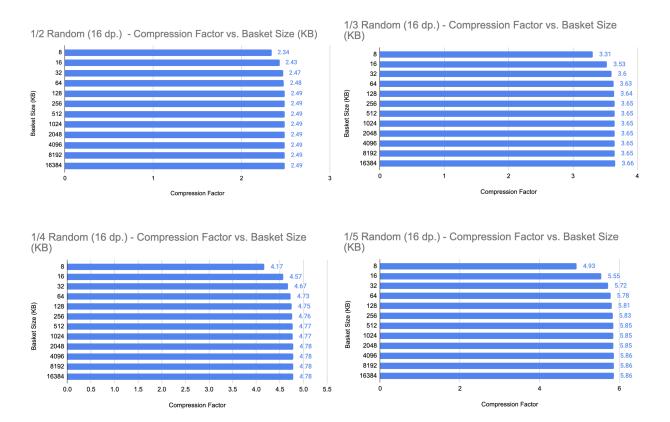

Figure 3.7: Varying Mixtures in 16 point precision - Number of Baskets vs Branch Size  $(N=10^6~{\rm events})$ 

#### CHAPTER 4

556

557

567

571

574

#### DATA AND MONTE CARLO DERIVATION PRODUCTION

Derivation production demands high memory usage, and DAODs make up a bulk of disk-558 space usage. DAODs are used in physics analyses and ought to be optimized to alleviate 559 stress on the GRID and to lower disk-space usage. Optimizing both disk-space and memory usage is a tricky balance as they are typically at odds with one another. For example, 561 increasing memory output memory buffers results in lower disk-space usage due to better compression but the memory usage will increase since the user will load a larger buffer into 563 memory. This project opted to take is by optimizing for disk-space and memory by testing 564 various basket limits and viewing the effects of the branches on both data and Monte Carlo 565 (MC) simulated analysis object data (AODs). 566

#### Basket-size Configuration 4.1

As the toy model ruled out, the focus here was on optimizing Athena and not ROOTs 568 contribution for optimization. The initial focus was on the inclusion of a minimum number of entries per buffer and the maximum basket buffer limit. The AthenaPOOL script directly involved with these buffer settings is the PoolWriteConfig.py found in the path athena/Database/AthenaPoOL/AthenaPoolCnvSvc/python/. As discussed in Section §??, further testing opted to keep the minimum number of entries set to its default setting, 10 573 entries per buffer.

Throughout the duration of this testing, the results of compression or file size are inde-575 pendent of any changes to the release or the nightly version of Athena. The data derivation 576

job comes from a 2022 dataset with four input files and 160,327 events. The MC job comes from a 2023  $t\bar{t}$  standard sample simulation job with six input files and 140,000 events. The datasets are noted in Appendix ??.

#### 4.1.1 Derivation Job Command

580

To run a derivation job, AODs need to be downloaded by data-management service, such as Rucio, to a users local machine. Rucio is the data-management solution used for this project to procure the various AOD input files used for the derivation jobs. The machine running the Rucio client will need to have a valid proxy added for Rucio to run correctly. A sample command would look like:

```
586 | rucio download data22_13p6TeV:AOD.31407809._000898.pool.root.1
```

This downloads the AOD file from Rucio and saves it to the user's local directory.

The command used by Athena to run a derivation job takes the form of the following example:

```
ATHENA_CORE_NUMBER=4 Derivation_tf.py \
593
   --CA True \
594
   --inputAODFile mc23_13p6TeV.601229.PhPy8EG_A14_ttbar_hdamp258p75_SingleLep
595
       .merge.AOD.e8514_e8528_s4162_s4114_r14622_r14663/AOD.33799166._001224.
596
       pool.root.1 \
   --outputDAODFile art.pool.root \
598
   --formats PHYSLITE \
   --maxEvents 2000 \
600 (
   --sharedWriter True \
601
   --multiprocess True ;
602
603
```

Where Athena allows one to specify the number of cores to use with the ATHENA\_CORE\_NUMBER environment variable. Derivation\_tf.py is a script that runs the derivation job and is part of the Athena release. The --inputAODFile is the input file for the derivation job, in this case an AOD file. The user can specify multiple input files at a time by enclosing the input files in quotes and separating each file with a comma, like the following:

```
--inputAODFile="AOD.A.pool.root.1,AOD.B.pool.root.1,AOD.C.pool.root.1,

AOD.D.pool.root.1"
```

The --outputDAODFile is the output file for the derivation job, in this case a DAOD file.

The --formats PHYSLITE flag allows the job to use the PHYSLITE format for the DAOD.

Here is where the user may choose to include PHYS or PHYSLITE simply by inlusion of one or both. The --maxEvents flag allows one to specify the maximum number of events to run the job on. The --sharedWriter True flag allows the job to utilize SharedWriter. The --multiprocess True flag allows the job to use AthenaMP tools.

The input files for both data and MC jobs were ran with various configurations of Athena by modifying the basket buffer limit. The four configurations tested all kept minimum number of basket buffer entries at 10 and modified the basket limitation in the following ways:

- 1. "default" Athena's default setting, and basket limit of  $128 \times 1024$  bytes
- 624 2. "256k" Limit basket buffer to  $256 \times 1024$  bytes
- 3. "512k" Limit basket buffer to  $512 \times 1024$  bytes
- 4. "no-lim" Removing the Athena basket limit, the ROOT imposed 1.3 MB limit still remains

628 4.2 Results

## 4.2.1 Presence of basket-cap and presence of minimum number of entries

First batch testing was for data and MC simulation derivation production jobs with and without presence of an upper limit to the basket size and presence of the minimum number of basket buffer entries. PHYSLITE MC derivation production, from Table ??, sees a 9.9% increase in output file size when compared to the default Athena configuration. Since this configuration only differs by the omission of the "min-number-entries" requirement, we assume the minimum number of basket buffer entries should be kept at 10 and left alone. Table ?? also shows the potential for a PHYSLITE MC DAOD output file size reduction by eliminating our upper basket buffer limit altogether.

Presence of features (Data)	Max PSS (MB) ( $\Delta$ % default)	PHYS outFS (GB) ( $\Delta$ %)	PHYSLITE outFS (GB) ( $\Delta$ %)
basket-cap, min-num-entries (default)	27.1 ( + 0.0 %)	3.22 (+0.0 %)	1.03 ( + 0.0 %)
basket-cap min-num-entries	27.8 ( + 2.5 %)	3.22 ( + 0.2 %)	1.04 ( + 0.2 %)
basket-cap min-num-entries	27.8 ( + 2.5 %)	3.22 ( - 0.0 %)	1.03 ( - 0.4 %)
basket-cap, min-num-entries	27.3 ( + 0.7 %)	3.22 ( + 0.2 %)	1.04 ( + 0.7 %)

Table 4.1: Comparing the maximum proportional set size (PSS) and PHYS/PHYSLITE output file sizes (outFS) for data jobs while varying the presence of features in Athena PoolWriteConfig.py for 160327 entries.

Presence of features (MC)	Max PSS (MB) ( $\Delta$ % default)	PHYS outFS (GB) ( $\Delta$ %)	PHYSLITE outFS (GB) ( $\Delta$ %)
basket-cap, min-num-entries (default)	14.1 ( + 0.0 %)	5.8 ( + 0.0 %)	2.6 (+0.0 %)
basket-cap min-num-entries	16.1 ( + 12.1 %)	6.0 ( + 2.9 %)	2.7 ( + 5.1 %)
basket-cap min-num-entries	16.0 ( + 11.5 %)	5.7 ( - 2.8 %)	2.5 ( - 5.6 %)
basket-cap, min-num-entries	14.2 ( + 0.4 %)	6.2 ( + 5.4 %)	2.9 ( + 9.9 %)

Table 4.2: Comparing the maximum proportional set size (PSS) and PHYS/PHYSLITE output file sizes (outFS) for MC jobs while varying the presence of features in Athena PoolWriteConfig.py for 140000 entries.

629

#### 4.2.2 Comparing different basket sizes

639

Pre-existing derivation jobs were ran for data and MC simulations to compare between configurations of differing basket sizes limits. The results for this set of testing are found from Table ?? through Table ??. The following tables are the DAOD output-file sizes of the various Athena configurations for PHYS/PHYSLITE over their respective data/MC AOD input files.

Athena Configs (Data)	Max PSS (MB) ( $\Delta\%$ default)	PHYS outFS (GB) ( $\Delta\%$ )	PHYSLITE outFS (GB) ( $\Delta\%$ )
(default)	27.9 ( + 0.0 %)	3.3 ( + 0.0 %)	1.0 ( + 0.0 %)
256k_basket	28.2 ( + 1.3 %)	3.3 ( - 0.1 %)	1.0 ( - 0.3 %)
512k_basket	28.5 ( + 2.2 %)	3.3 ( + 0.0 %)	1.0 ( - 0.3 %)
1.3 MB (ROOT MAX)	28.6 ( + 2.7 %)	3.3 ( - 0.1 %)	1.0 ( - 0.3 %)

Table 4.3: Comparing the maximum proportional set size (PSS) and PHYS/PHYSLITE output file sizes (outFS) for Data jobs over various Athena configurations for 160327 entries.

Athena Configs (Data)	Max PSS (MB) ( $\Delta$ % default)	PHYS outFS (GB) ( $\Delta\%$ )	PHYSLITE outFS (GB) ( $\Delta\%$ )
(default)	15.0 ( + 0.0 %)	5.9 ( + 0.0 %)	2.6 (+0.0 %)
256k_basket	15.3 ( + 1.9 %)	5.8 ( - 1.4 %)	2.5 ( - 3.1 %)
512k_basket	16.4 ( + 8.6 %)	5.7 ( - 2.5 %)	2.5 ( - 5.1 %)
1.3 MB (ROOT MAX)	16.9 ( + 11.3 %)	5.7 ( - 2.8 %)	2.5 ( - 5.6 %)

Table 4.4: Comparing the maximum proportional set size (PSS) and PHYS/PHYSLITE output file sizes (outFS) for MC jobs over various Athena configurations for 140000 entries.

"Max PSS" refers to the maximum proportional set size, which is the maximum memory usage of the job. Table ?? tells us that with this  $t\bar{t}$  data sample, there are marginal changes in both the memory usage for the job and the output file size of the DAODs. Whereas Table ?? shows a much more drastic change, with a 5.6% reduction in output file size for the MC PHYSLITE DAOD when compared to the default Athena configuration. While there's a 5.6% reduction in output file size for the MC PHYSLITE DAOD, there's also a 11.3% increase in memory usage.

# 4.2.3 Monte Carlo PHYSLITE branch comparison

652

Derivation production jobs work with initially large, memory-consuming branches, com-653 pressing them to a reduced size. These derivation jobs are memory intensive because they 654 first have to load the uncompressed branches into readily-accessed memory. Once they're 655 loaded, only then are they able to be compressed. The compression factor is the ratio of prederivation branch size (Total-file-size) to post-derivation branch size (Compressed-file-size). 657 The compressed file size is the size of the branch that is permanently saved into the DAOD. Branches with highly repetitive data are better compressed than non-repetitive data, 659 leading to high compression factors—the initial size of the branch contains more data than it needs pre-derivation. If pre-derivation branches are larger than necessary, there should be 661 an opportunity to save memory usage during the derivation job. 662

The following tables look into some highly compressible branches that might lead to areas
where simulation might save some space.

Athena v24.0.16 (default) MC branch	Branch size (kB)	Total-file-size (MB)	Compressed-file-size (MB)	Compression factor
Primary Vertices Aux Dyn. track Particle Links	128	2146.2	24.0	89.4

Table 4.5: Top 10 branches sorted by compression factor, MC PHYSLITE [Athena v24.0.16 default configuration.]

An immediate observation: with the omission of the Athena basket limit (solely relying on ROOTs 1.3MB basket limit), the compression factor increases. This is inline with
the original expectation that an increased buffer size limit correlate to better compression.

Primary Vertices Aux Dyn. track Particle Links is a branch where, among each configuration of
Athena MC derivation, has the highest compression factor of any branch in this dataset.

Athena v24.0.16 (no-lim) MC branch	Branch size (kB)	Total-file-size (MB)	Compressed-file-size (MB)	Compression factor

Table 4.10: Top 10 branches sorted by compressed file size in bytes, MC PHYSLITE [Athena v24.0.16 without limit to the basket buffer.]

Some branches, like *HLTNav Summary DAODSlimmedAuxDyn.linkColNames* show highly compressible behavior and are consistent with the other job configurations (data, MC, PHYS, and PHYSLITE). Further work could investigate these branches for further areas of optimization for long term storage and better memory usage during derivation.

# 4.3 Conclusion to derivation job optimization

674

Initially, limiting the basket buffer size looked appealing; after the 128 kB basket buffer size limit was set, the compression ratio would begin to plateau, increasing the memory-usage without saving much in disk-usage. The optimal balance is met with the setting of 128 kB basket buffers for derivation production.

Instead, by removing the upper limit of the basket size, a greater decrease in DAOD output file size is achieved. The largest decrease in file size came from the PHYSLITE MC derivation jobs without setting an upper limit to the basket buffer size. While similar decreases in file size appear for derivation jobs using data, it is not as apparent for data as it is for MC jobs. With the removal of an upper-limit to the basket size, ATLAS stands to gain a 5% decrease for PHYSLITE MC DAOD output file sizes, but an 11 – 12% increase in memory usage could prove a heavy burden (See Tables ?? and ??).

By looking at the branches per configuration, specifically in MC PHYSLITE output 686 DAOD, highly compressible branches emerge. The branches inside the MC PHYSLITE 687 DAOD are suboptimal as they do not conserve disk space; instead, they consume mem-688 ory inefficiently. As seen from Table ?? through ??, we have plenty of branches in MC 689 PHYSLITE that are seemingly empty—as indicated by the compression factor being  $\mathcal{O}(10)$ . 690 Reviewing and optimizing the branch data could further reduce GRID load during DAOD 691 production by reducing the increased memory-usage while keeping the effects of decreased 692 disk-space. 693

701

### MODERNIZING I/O CI UNIT-TESTS

Athena uses a number of unit tests during the development lifecycle to ensure core I/O functionality does not break. Many of the I/O tests were originally created for the old EDM and haven't been updated to test the xAOD EDMs core I/O functions. This project took in track information from a unit test using the T/P EDM, writes the data into an example xAOD object to file and reads it back.

### 5.1 xAOD Test Object

The object used to employ the new unit test is the xAOD::ExampleElectron object, where 702 the xAOD: is a declaration of the namespace and simply identifies the object as an xAOD 703 object. An individual ExampleElectron object only has a few parameters for sake of testing, 704 its transvese momentum, pt, and its charge, charge. A collection of ExampleElectron 705 objects are stored in the ExampleElectronContainer object, which is just a DataVector 706 of ExampleElectron objects. [Buckley'2015] This DataVector<xAOD::ExampleElectron> 707 acts similar to a std::vector<xAOD::ExampleElectron>, but has additional code to handle 708 the separation of interface and auxiliary data storage. 709

The xAOD EDM uses an abstract interface connecting between the DataVector and the
auxiliary data, this is the IAuxStore. The function setStore is responsible for ensuring
the auxiliary data store is matched with it's corresponding DataVector. Another feature to
the xAOD EDM is the ability to have a dynamic store of auxiliary data. This separates the
auxiliary data between static and dynamic data stores. Where the static dta stores comprise

of known variables and the dynamic counterpart stores data of variables not declared but 715 still might be needed by the user. Figure ?? illustrates how a simple setup of storing a 716 DataVector of electrons that hold some specific parameters into one IAuxStore while also having a separate IAuxStore specifically for the dynamic attributes.

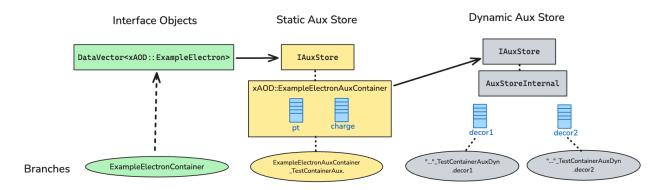

Figure 5.1: The framework between interface objects and the static/dynamic auxiliary data store for a collection of xAOD::ExampleElectrons.

5.2 Unit Tests

719

721

724

Unit tests are programs that act as a catch during the continuous integration of a codebase 720 and exhaust features that need to remain functional. Athena has a number of unit tests which check every merge request and nightly build for issues in the new code that could 722 break core functionality, either at the level of Athena, ROOT, or any other software in the 723 LCG stack. With the adoption of the xAOD EDM, there were no unit tests to cover core I/O functionality related to this new EDM. 725

Specifically there were no unit tests to handle selection of dynamic attributes, or decora-726 tions, on xAOD objects created during writing and read back. To address this, a new xAOD 727 test object needed to be created and written during a new unit test that fit into the existing 728 unit tests. The list of AthenaPoolExample unit tests that are currently executed during a 729

nightly build can be found in Table ??. These tests are executed in this order, as the objects created in one might be used in proceeding test.

Unit Test	Employed Algorithms
Write	WriteData
ReadWrite	ReadData
Read	ReadData
Сору	None
ReadWriteNext	ReadData, ReWriteData
WritexAODElectron	ReadData, WriteExampleElectron
ReadxAODElectron	ReadExampleElectron
ReadAgain	ReadData
WriteConcat	WriteData, ReWriteData
ReadConcat	ReadData
WriteCond	ReadData, WriteCond
ReadCond	ReadData, ReadCond
WriteMeta	WriteData, WriteCond
ReadMeta	ReadData

Table 5.1: List of unit tests in the AthenaPoolExample package that are currently executed during a nightly build.

The mechanism for passing a unit test is done automatically by building the framework, running the unit tests, and comparing the diff of the output file to the unit test with a reference file associated with that particular unit test. If the unit test passes, then the diff, a product of the git diff command, will be empty and the unit test will be marked as passing. Conversely, if the unit test fails, then the diff will be non-empty and the unit test will be marked as failing.

#### 5.2.1 WritexAODElectron.py

738

The two new tests added to the package were WritexAODElectron and ReadxAODElectron.

During this first unit test, the first algorithm called is to ReadData which reads off all of
the ExampleTrack objects stored in one of the files produced by the ReadWrite unit-test.

Within the python script of the first unit test, the user is able to decide what decorations to have written to file. This is a part of the OutputStreamCfg parameter, ItemList, wherein the user specifies the object and its name in the format shown in Figure ??.

```
ItemList = [ "ExampleTrackContainer#MyTracks",
    "xAOD::ExampleElectronContainer#TestContainer",
    "xAOD::ExampleElectronAuxContainer#TestContainerAux.-decor2"] )
```

Figure 5.2: WritexAODElectron ItemList for the OutputStreamCfg parameter. Showing how to select dynamic attributes at the CA level.

Much of the code in Athena practice header/source-file separation, the header acting 745 as an interface for the whole object and the source file containing the core functionality of 746 the algorithm. The header file includes various packages needed by the algorithm, such as 747 data objects, Write/ReadHandleKeys, base algorithms that give consistent structure to the 748 algorithm, and whatever else is required. In the write-algorithm, there are ReadHandleKeys 749 for ExampleTrack objects saved by a prior unit test. For the WriteHandleKeys, there is 750 one for the ExampleElectronContainer and the name given to it is "TestContainer". This 751 "TestContainer" name will be needed for the ReadExampleElectron algorithm as the name 752 is how it's able to refer to the correct ExampleElectronContainer present in the input file. 753 Additionally, a WriteHandleDecorKey for the decoration objects is needed for appending 754 each decoration onto each ExampleElectron object. Figure ?? shows the syntax for how 755 these keys would be presently defined.

Then the WriteExampleElectron algorithm is called and takes ExampleTracks, creates
an ExampleElectron object and sets the electrons pt to the tracks pt. As shown in Figure
??, the ExampleElectronContainer and ExampleElectronAuxContainer are created and
set to the elecCont and elecStore respectively. The elecCont has an associated aux store,
so the setStore function is called with the elecStore pointer. The track container is
accessed by using StoreGate's ReadHandle, which associates the m\_exampleTrackKey with

```
// Read key ExampleTracks
  SG::ReadHandleKey < ExampleTrackContainer > m_exampleTrackKey {
      this, "ExampleTrackKey", "MyTracks"};
  // Write key for the ExampleElectronContainer
  SG::WriteHandleKey <xAOD::ExampleElectronContainer>
      m_exampleElectronContainerKey{this, "ExampleElectronContainerName",
                                   "TestContainer"};
  // Decoration keys
  SG::WriteDecorHandleKey < xAOD::ExampleElectronContainer > m_decor1Key {
      this, "ExampleElectronContainerDecorKey1", "TestContainer.decor1",
      "decorator1 key"};
13
  SG::WriteDecorHandleKey <xAOD::ExampleElectronContainer > m_decor2Key {
14
      this, "ExampleElectronContainerDecorKey2", "TestContainer.decor2",
15
      "decorator2 key"};
16
```

Figure 5.3: WriteExampleElectronheader file setup

the ExampleTrackContainer specified in the header file. This is then looped over all elements in the container and the pt of each track is set to the pt of the electron. A WriteHandle, called objs, is then created for the container of ExampleElectrons which is then recorded.

Within the same algorithm, the next step is to loop over each of the newly produced ExampleElectrons, accessing the decorations decor1 and decor2, and setting each to an arbitrary float value that are easily identifiable later. Figure ?? shows how this is done using two handles for each decoration. Note the difference here using the WriteDecorHandle, where the prior handle type was WriteHandle.

### 5.2.2 ReadxAODElectron.py

771

The only algorithm called in this test is ReadExampleElectron. The header file for
the ReadExampleElectron only creates ReadHandleKey for the container of ExampleElectrons, with the same name from the header of the WriteExampleElectron algorithm header,
syntax shown in Figure ??. From the source file, we can initialize the ReadHandleKey

```
auto elecCont = std::make_unique < xAOD::ExampleElectronContainer > ();
auto elecStore = std::make_unique < xAOD::ExampleElectronAuxContainer > ();
elecCont -> setStore(elecStore.get());

SG::ReadHandle < ExampleTrackContainer > trackCont(m_exampleTrackKey, ctx);
elecCont -> push_back(std::make_unique < xAOD::ExampleElectron > ());

for (const ExampleTrack* track : *trackCont) {
    // Take on the pT of the track
    elecCont -> back() -> setPt(track -> getPT());
}

SG::WriteHandle < xAOD::ExampleElectronContainer > objs(
    m_exampleElectronContainerKey, ctx);
ATH_CHECK(objs.record(std::move(elecCont), std::move(elecStore)));
```

Figure 5.4: Algorithm to initialize and write T/P data (ExampleTracks) to an xAOD object container (ExampleElectronContainer).

```
SG::WriteDecorHandle < xAOD::ExampleElectronContainer, float > hdl1(
    m_decor1Key,ctx);
SG::WriteDecorHandle < xAOD::ExampleElectronContainer, float > hdl2(
    m_decor2Key,ctx);

for (const xAOD::ExampleElectron* obj : *objs) {
    hdl1(objs) = 123.;
    hdl2(objs) = 456.;
}
```

Figure 5.5: Writing of dynamic variables for each of the ExampleElectron objects.

object by a simple ATH\_CHECK(m\_exampleElectronContainerKey.initialize()); in the intitialize() method. This allows for, when defining the ReadHandle in execute, identifying the correct container defined in the header file. The same can be done for the decoration key, which needs a separate read handle, ReadDecorHandle. Once this is setup, all the read algorithm needs to do is to loop over all the ExampleElectrons in the "TestContainer" and access their  $p_T$  and charge.

```
SG::ReadHandleKey<xAOD::ExampleElectronContainer>
m_exampleElectronContainerKey{this, "ExampleElectronContainerName",
"TestContainer"};
```

Figure 5.6: ReadHandleKey for the container of ExampleElectrons

782 5.3 Results

This project sought to replace existing unit tests that created ExampleHits, T/P EDM objects, to be written and read back. An independent xAOD object, ExampleElectron, was created and implemented into two new unit tests that write and read ExampleElectron objects along with their chosen dynamic attributes. A merge request was created, approved, and merged into the Athena software framework. Future work can be done to fully modernize the package these unit tests reside, AthenaPoolExampleAlgorithms, including unit tests that test core functionality of AthenaMT/AthenaMP, and newer storage formats like RNTuple.

### CHAPTER 6

#### CONCLUSION

The work done for this thesis was primarily motivated to find avenues to optimize resource usage for GRID I/O operations.

The toy model testing allowed us to create branches with data similar compression ratios to real and simulated data, allowing to investigate the hypothesis that modifying the basket buffer limit had an effect on disk and memory usage. It led to the conclusion that, upon investigating with real data and real MC simulation, that there might be an avenue to look at both ROOT and Athena to limit basket sizes.

Modifying the basket buffer sizes at the Athena level shows there was a balance was struck when using the Athena basket buffer size limited to 128 kB between memory-usage and the size of the DAOD to be saved long-term. Removing the basket buffer size limit, the 5.5% saving in PHYSLITE MC disk-usage at the expense of an 11% increase in memory-usage could be a trade-off worth making in some scenarios. A class of potentially unoptimized AOD branches in MC simulated data was also brought to light during this study. The leading indicator to potential optimization is the highly compressible nature of these branches post-derivation. Further work could be done to look into these AOD branches to identify areas where further work can be done to reduce.

The xAOD EDM comes with a number of new additions to bring about optimization the future of analysis work at the ATLAS experiment. Integrating the new features into a few comprehensive unit tests allow for the nightly CI builds to catch any issues that break core I/O functionality as it pertains to the xAOD EDM, which has not been done before. These

 $_{\mbox{\scriptsize 812}}$  new unit-tests exercise reading and writing select decorations ontop of the already existing

 $_{\mbox{\scriptsize 813}}$  data structures attacted to an example object called  $\mbox{\tt ExampleElectron}.$
